## Latest Documented Fall record of *Oporornis agilis* (Connecticut Warbler) in North America

Noah Perlut\*

**Abstract** - On 11 November 2017, a male hatch-year *Oporornis agilis* (Connecticut Warbler) was killed by a *Felis catus* (Domestic Cat) in Scarborough, Cumberland County, ME. This specimen, housed in the University of New England ornithological collection, is the latest documented fall record of this species in North America.

During fall migration, *Oporornis agilis* (Wilson) (Connecticut Warbler) migrate south and east from their breeding grounds to the eastern coast of North America before flying over open ocean to islands in the eastern Caribbean and then to South America (McKinnon et al. 2017). On 11 November 2017, a male hatch-year Connecticut Warbler was killed by a *Felis catus* (L.) (Domestic Cat) near Thomas Drive, Scarborough, Cumberland County, ME (latitude 43.5589°N, longitude 70.3200°W). To my knowledge, this is the latest verified fall record of Connecticut Warbler in mainland North America, and is notably later than other records for the northeastern US. The latest bird-banding capture of Connecticut Warbler at equal or greater latitude in North America is 15 October (Alpena, Michigan; USGS 2018). Peak frequency of reports along the east coast of the US is 15 September, with nearly all migrants occurring from late August to late October (eBird 2018a).

Previously, the latest record for Maine was a sight record with photographs from 12 October 2015 in York County (eBird 2018b). From north to south, latest reported sight records or banding records (USGS 2018) for this species include: Ontario 19 October (USGS 2018), Nova Scotia 18 October (McLaren 2012), New Hampshire 13 October (Keith and Fox 2013), Vermont 21 October (eBird 2018c), Massachusetts 26 October (Veit and Petersen 1993), Rhode Island 27 October (USGS 2018), Connecticut 31 October (Zeranski and Baptist 1990), New York 30 October (Levine 1998), New Jersey 31 October (USGS 2018), Delaware 24 October (Hess et al. 2000), Maryland 7 November (Stewart and Robbins 1958), Virginia 29 October (USGS 2018), and Bermuda 3 November (eBird 2018d).

Connecticut Warbler vacates mainland North America during winter (Pitocchelli et al. 2012). Although Christmas Bird Counts spanning 15–31 December from 1967 to 2013 have reported the species 14 times (National Audubon Society 2018), none of those observations is documented by a photograph, preserved specimen, or measurements. A banding report for 16 November at Vero Beach, FL (USGS 2018), may constitute a later fall record than the Maine bird, although this record is also not documented by a photograph or measurements. Connecticut Warbler is frequently misidentified, especially in fall when immatures and females can be confused with both *Geothlypis philadelphia* (Wilson) (Mourning Warbler) and *G. trichas* (L.) (Common Yellowthroat) and vice versa. In fact, I originally misidentified this bird as a Mourning Warbler, until more detailed study of its plumage and morphology identified it as a Connecticut Warbler. Therefore, verifiable evidence in the form of a photograph or specimen is often necessary to document extra-limital records and extreme dates of occurrence.

I made the following morphological measurements, which allowed diagnostic identification, from the Maine specimen: wing chord = 67.5 mm, flattened wing length = 68 mm, length of p9–length of p6 = 5.5 mm, tail = 49 mm, tarsus = 20.71 mm, bill width = 2.90 mm, bill length = 8.08 mm, bill depth = 3.16 mm, mass = 13.8 g, spread wing = 160 mm, and total body length = 130 mm. I sexed the bird as male (testes present), and aged it as a hatch-year in formative plumage (juvenile rectrices pointed; incomplete skull ossification). The wing chord exceeded the known maximum for Mourning Warbler, and the p9–p6 difference was likewise longer than known for Mourning Warbler (Lanyon and Bull 1967, Pitocchelli et al. 2012). The Maine specimen shows a bold, whitish-buff eye ring combined with a brownish buff throat cut off sharply at the breast, characteristic of the Connecticut Warbler. The Mourning Warbler has, at most, a thin eye ring that is narrowly broken both anteriorly and posteriorly, a yellow wash to the chin and throat, and lacks a sharp border between throat and breast. A narrow break in the eye ring posteriorly behind the eye often occurs on immature Connecticut Warblers, as was the case for the Maine bird. Its dull yellow underparts also differed from the bright yellow typical of the Mourning Warbler. The specimen is housed in the Department of Environmental Studies ornithology collection at the University of New England, Biddeford, ME (reference identification: UNE 057). I encourage others to make careful observations and measurements of this species, where possible, to provide a more detailed understanding of the location and timing of movement by Connecticut Warblers. Finally, this record serves as a continuing call to mediate the impacts of free-ranging Domestic Cats on birds (e.g., Loss et al. 2013), including relatively rare species like the Connecticut Warbler.

*Acknowledgments.* This work was supported by the University of New England. Major thanks to L. Bevier, for his thoughtful support. E. White took all morphological measurements; L. Moser prepared the specimen for the museum collection. CBC Data is provided by National Audubon Society and through the generous efforts of Bird Studies Canada and countless volunteers across the western hemisphere.
